# Easy projection of stereo movies

## Noel Bartlett, G Andrew Erickson, Donald H J Mackay and Kent R Wilson

Department of Chemistry, University of California, San Diego, La Jolla, CA 92093, USA

A method is described of showing colour stereo movies with arbitrary movie projectors by means of a small portable adapter. The beam from an ordinary movie projector is passed through a linear polarizer and then a crystal, which rotates the angle of polarization under voltage control so that alternating left and right images are polarized 90° apart. A photodiode and a sensing circuit synchronize the polarization shift to the flicker of the projector shutter. The adapter is small and self contained and needs only to be placed in the path of the projected beam.

Keywords: projectors (image), stereo, movie, molecular graphics

Received 21 April 1986 Accepted 13 May 1986

The perception of depth is basic to our assimilation of information in a 3D world. In the field of chemistry, the 3D structure of molecules is essential to understanding the function, interaction and dynamics of chemical systems. However, with the exception of physical models, three dimensionality is largely limited to 2D projections. Several visual effects can be used to convey the impression of depth. Shading, intensity attenuation with depth, hidden surface removal and motion (particularly rotation) provide useful depth cues, which are usually sufficient for objects with which the mind has had previous 3D experience, such as models of automobiles or buildings. Molecular models, however, are abstract. Stereoscopic perception (each eye seeing a different perspective of the image allowing the brain to perceive the image in three dimensions) has therefore become very useful for visualizing complex molecular models, especially those composed of many atoms such as large biological molecules.

Stereo imaging has been accomplished in various ways, the simplest and oldest being the stereoscope, which places left and right images of a scene in front of the respective eyes and prevents each eye from seeing the other image. Several variations on this theme have been devised using more elaborate eye-image selection schemes and have been implemented using various media including television, printed material and computer graphics1. These include colour filtering (red and green images filtered through coloured glasses)2, polarized filtering (images composed of polarized light rotated 90° from each other and viewed through polarizing filters), mechanical shutters (rotating shutters that allow only one eye to see at a time, coupled with a synchronous display which shows the appropriate image for each eye) and electronic shutters (similar in concept to mechanical shutters but replacing the rotating disc or cylinder with

Screen

an electronically switched device, for example, a sandwich of polarization rotating crystal between polarizing filters)<sup>3,4</sup>.

Each of these techniques relies upon tricking the mind into perceiving a 3D image, using a pair of 2D images. In addition, 'true' 3D images can be reconstructed, for example holograms<sup>1</sup>. A novel approach uses a vibrating mirror to reflect a computer-generated image which is synchronized to the current position of the vibrating mirror<sup>5</sup>. True 3D representations have the advantage that one can perceive the same model from different viewpoints.

While each of these methods is useful in its own context, most are limited by the need for specialized, often expensive, equipment which can conveniently be used by only a few people at a time. One would like a simple and inexpensive means of conveying to larger audiences 3D information about systems that change with time, for example, the molecular dynamics by which chemical processes take place. Stereo movies have been made for many years, but they require specially modified (and usually expensive) projectors, which are often bulky (some schemes actually require two synchronized projectors) and are nonuniversal. A simple apparatus is described here which costs less than \$1000 and which enables any style or make of movie projector to display stereo films. The equipment is easily portable and has been tested over the past few years with a large variety

of commercial movie projectors. It could equally well be adapted to live action film or projection TV.

#### CONSTRUCTION

The technique requires that the film be prepared so that left and right images occur on alternate frames. In computer animated films, this is accomplished by shooting each image twice, alternating the perspective of the image by a small angle between exposures. To increase the stereo effect, the image to be viewed in 3D is rotated around a point that would be the back of the model if the image were physically present. The amount the image is rotated was experimentally derived to give an image that is as flickerless as possible but that also has a sufficient stereo 'depth'. A rotation of 1.75% of the picture width was found to produce the best quality 3D image. In addition, the use of perspective by shrinking the size of objects that are farther away helps the mind perceive the images in 3D. For noncomputeranimated films, specialized camera equipment is necessary. Standard techniques include mounting two cameras side by side to expose left and right images synchronously. The two films can then be interlaced using an optical printer. Alternatively, a single camera with a double lens and a left/right shutter, to select alternating lenses, can expose the left and right images directly.

The apparatus described here consists of four basic components:

- a polarization control assembly with an initial polarizing filter and a polished and electroded lead lanthanum zirconate titanate (PLZT) transparent ceramic wafer which can be voltage controlled to rotate polarized light (see Figure 1),
- a synchronizing circuit to monitor the flicker rate of the projector using a light-sensitive diode placed in the light path,
- a voltage-switching circuit to switch the voltage to the PLZT wafer between stereo pair frames,
- a power supply for the PLZT wafer.

The apparatus functions by a three-stage filtering process. First, the assembly polarizes the light to one particular orientation (for example, for left-eye viewing). Then, under voltage control, the PLZT wafer can rotate this light through 90°, thereby creating a right-eye image. When to rotate the image is determined by a sensing circuit which samples the flicker rate of the projector and switches the crystal voltage on and off on alternate frames. The final outcome is a stream of images com-

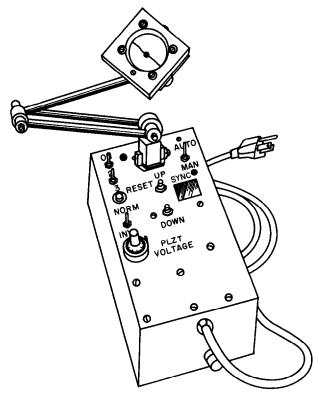

Figure 3. Physical representation of stereo projection unit and controls

posed of pairs of polarized frames rotated by 90° with respect to each other.

The image stream must then be reflected from a nondepolarizing screen. The final filtering occurs through polarizing spectacles worn by the viewer with the righteye filter oriented to exclude left images (i.e. oriented 90° relative to the incoming left-image light), and vice versa, producing the stereo effect by allowing left and right images to be seen only by their respective eyes.

The PLZT wafer is commercially available from Motorola's Ceramic Products Division\* and is produced in two thicknesses (0.05 cm and 0.1 cm) requiring different voltages (280 V and 520 V, respectively) and in various packages. We have found the lower voltage (thinner) wafer to be preferable, in spite of a 25% higher price, since the required voltage is more manageable. We have also found the bare ceramic wafer to be very fragile and prefer a glass sandwich package which protects it from breakage and humidity. The sandwiched version usually contains two polarizing filters oriented 90° relative to each other on either side of the filter to act as a voltage-dependent light shutter. Our application uses it as a voltage-dependent light rotator and so needs only the leading filter. We used a sandwich version without polarized filters.

The most general way to synchronize the polarization rotation is to sense frame advances by monitoring the light coming from the projector. This scheme is complicated by the fact that movie projectors divide each frame into several (almost always two or three) flashes to increase the apparent refresh rate and thereby reduce perceived flicker.

The circuit that monitors the flicker of the projector

consists of a photodiode which is placed directly in the path of the projected light. The projected image is not impaired because of the location away from the focal plane. As a pulse of light is received, the photodiode sends a pulse to the counter section of the circuitry composed of two, 4-bit, bidirectional serial-in, parallel-out shift registers and associated driver circuitry (U14 and U15 in Figure 2). The synchronization circuitry uses a comparator (U2) and locking circuitry (U4) so that when synchronization occurs, the apparatus stays locked. The manual sync circuitry consists of an LED display, which indicates how many fractions of a frame the operator has changed from the original synchronization, and two buttons, which allow the synchronization to be shifted either forward or backward. The output of the synchronization circuitry used to control the voltage to the PLZT is taken from the second or third bit of the shift register, depending on whether the particular projector cuts each frame into two or three flashes. To simplify the procedure of synchronization, an autosynchronization feature is provided which uses a test leader of alternating black and white frames inserted at the beginning of each movie. The photodiode is able to distinguish between black and white frames, and therefore the unit can synchronize itself to these frames (when in autosynchronization mode) on the leader and relieve the operator of any manual intervention. Owing to the sensitivity of the photodiode in the infrared, and the transparency of even black frames of film in the infrared, the unit remains synchronized throughout the movie.

The voltage required for the PLZT wafer is controlled by a high voltage switching transistor which alternately turns a 325 V power supply on or off with every frame pulse. The power supply can be varied from 250 V to 400 V, to correct for any differences in PLZT crystals and to balance the colour and intensity of the left and right images. With the proper voltage setting, the colours of the projected images are virtually undistorted.

#### **DISCUSSION**

The overall stereo effect is very impressive. The main disadvantage of this method is that the effective refresh rate of standard movies is reduced from 24 frames/s to 12. Thus a noticeable, but not objectionable, flicker is present. This could be cured by increasing the speed of the projector, but this would again lead to a nonportable system. The entire apparatus described above fits into a box, 30 cm by 13 cm by 8 cm and is ideal for travelling (see Figure 3). We feel this portability and usability with any projector far outweighs the small degradation in flicker perception.

#### **NOTE IN PRESS**

An improved and corrected circuit schematic, with a more detailed parts list, is available from Kent R Wilson at the address on p 190.
